

New basal dinosauromorph records from the Dockum Group of Texas, USA

Volkan Sarigül

ABSTRACT

The basal dinosauromorphs constitute an important component of the Late Triassic Dockum dinosauromorph diversity. This study introduces nine hitherto unpublished hind limb elements of basal dinosauromorphs from Garza and Randall counties in Texas. Most of these specimens consist of femoral and tibial fragments referred to *Dromomeron*, whereas one complete and one partial fibula resemble the morphology of *Marasuchus lilloensis*, but with much larger size, and are assigned to undetermined dinosauriforms. The discovery of three *Dromomeron* specimens in the Tecovas Formation of the Palo Duro Canyon are particularly noteworthy because these are the lowest occurrences of *Dromomeron romeri* and *Dromomeron gregorii*, and the first reported biostratigraphic overlap of the two taxa. The extended taxonomic range of *D. romeri* challenges its suggested replacement for *D. gregorii* in the Late Triassic (Adamanian-Revueltian) faunal turnover.

INTRODUCTION

The Dinosauromorpha (Benton, 1985) was one of the first clades erected after the introduction of cladistic approach to fossil archosaur studies. Since dinosaurs (including birds) comprise the majority of the dinosauromorphs, the terminology of "non-dinosaurian Dinosauromorpha" or "basal Dinosauromorpha" is useful to cover the close out-groups to the Dinosauria (e.g., Nesbitt et al., 2009; Langer et al., 2013). Early members of this out-

group like *Lagerpeton chanarensis* and *Marasuchus lilloensis* were discovered in the Chañares Formation (Romer, 1971, 1972), and the basal dinosauromorph fossil record remained restricted to Argentina for the following decades. Larger taxonomic diversity and wider dispersal patterns of these animals during the Mid and Late Triassic were revealed only after new discoveries from the early twenty-first century (e.g., Dzik, 2003; Irmis et al., 2007b; Ferigolo and Langer, 2007; Nesbitt et

Sarigül, Volkan. 2016. New basal dinosauromorph records from the Dockum Group of Texas, USA. *Palaeontologia Electronica* 19.2.21A: 1-16

al., 2009, 2010; Kammerer et al., 2012; Peecook et al., 2013; Barrett et al., 2015).

Non-dinosaurian dinosauromorphs are also represented in the Upper Triassic terrestrial sediments of the southwestern North America. *Technosaurus smalli* (Chatterjee, 1984) and *Eucoelophysis baldwini* (Sullivan and Lucas, 1999) are the two contemporary silesaurids from the Dockum Group and the Chinle Formation, respectively, which were originally considered as dinosaurs (Nesbitt et al., 2007; Irmis et al., 2007a). Probably the most significant contribution to the North American dinosauromorph studies was the discovery of the new basal dinosauromorph taxon *Dromomerion* (Irmis et al., 2007b). *Dromomerion* has two species described so far in North America, *D. romeri* and *D. gregorii*, of which the holotypes were, respectively, collected from the Hayden Quarry of the Petrified Forest Member (Chinle Formation) and the Otis Chalk Quarry 3 of the Colorado City Formation (Dockum Group) (Irmis et al., 2007b; Nesbitt et al., 2009). Together with *Lagerpeton chanarensis*, the two *Dromomerion* species are grouped in the clade Lagerpetidae, the basal-most dinosauromorph clade (Nesbitt et al., 2009). Various other specimens have been assigned to *Dromomerion romeri* and to silesaurids coming from the Late Triassic sediments of the Eagle Basin in northwestern Colorado (Small, 2009; Langer et al., 2013).

All of the Dockum non-dinosaurian dinosauromorphs have been collected from the Texas outcrops of the Dockum Group, including the holotype of *Technosaurus smalli* (Chatterjee, 1984), the holotype of *Dromomerion gregorii* together with their paratypes and a referred femur (Nesbitt et al., 2009; Martz et al., 2013), and an undetermined dinosauriform tibia that has affinities with silesaurids (Nesbitt and Chatterjee, 2008; Martz et al., 2013). Complementing the previous studies, the description of the unpublished non-dinosaurian dinosauromorph specimens provided here represents the most recent work on the subject.

Geological Setting and Fossil Localities

Continental sedimentation in the southwestern portion of North America during the Late Triassic was greatly influenced by a huge palaeoriver system named Chinle-Dockum (Riggs et al., 1996), which deposited large volumes of fluvial sediments. Comprising the upstream portion of this ancient river system, the Dockum Group sediments cover vast areas in the western part of Texas and the eastern part of New Mexico (Figure 1). The classical lithostratigraphic framework for the Doc-

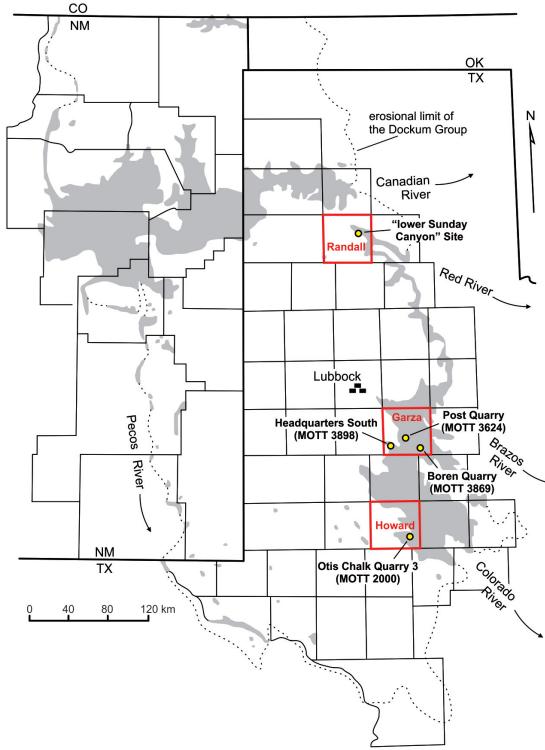

FIGURE 1. The Dockum Group exposures (highlighted in grey) in western Texas and eastern New Mexico (modified after Lehman, 1994a). Fossil localities are spotted (yellow-filled circles) within the corresponding counties of Garza, Howard and Randall (marked in red).

kum Group of Texas is provided by Lehman and Chatterjee (2005). In this scheme, the Dockum fluvial deposition is represented by two sequences: a thinner (less than 80 m) older sequence consisting of the Santa Rosa and Tecovas formations and a thicker (over 150 m) younger sequence consisting of the Trujillo and Cooper Canyon formations. The two sequences are separated by the "Tr-4" unconformity (Lucas and Anderson, 1993a). In the same work, both sequences are characterized by a fining-upward sequence that starts with basal fluvial channel sandstones (i.e., Santa Rosa and Trujillo formations) and grade into floodplain mudstone and claystone deposits (i.e., Tecovas and Cooper Canyon formations).

Sedimentology and lithostratigraphy of the Dockum Group were recently revisited in southern Garza County (Martz, 2008; Martz et al., 2013). In this work, problems with the lithologic boundaries of the Cooper Canyon Formation were recognized for the first time. Originally coined as the Cooper Member (Chatterjee, 1986), this is a thick mud-

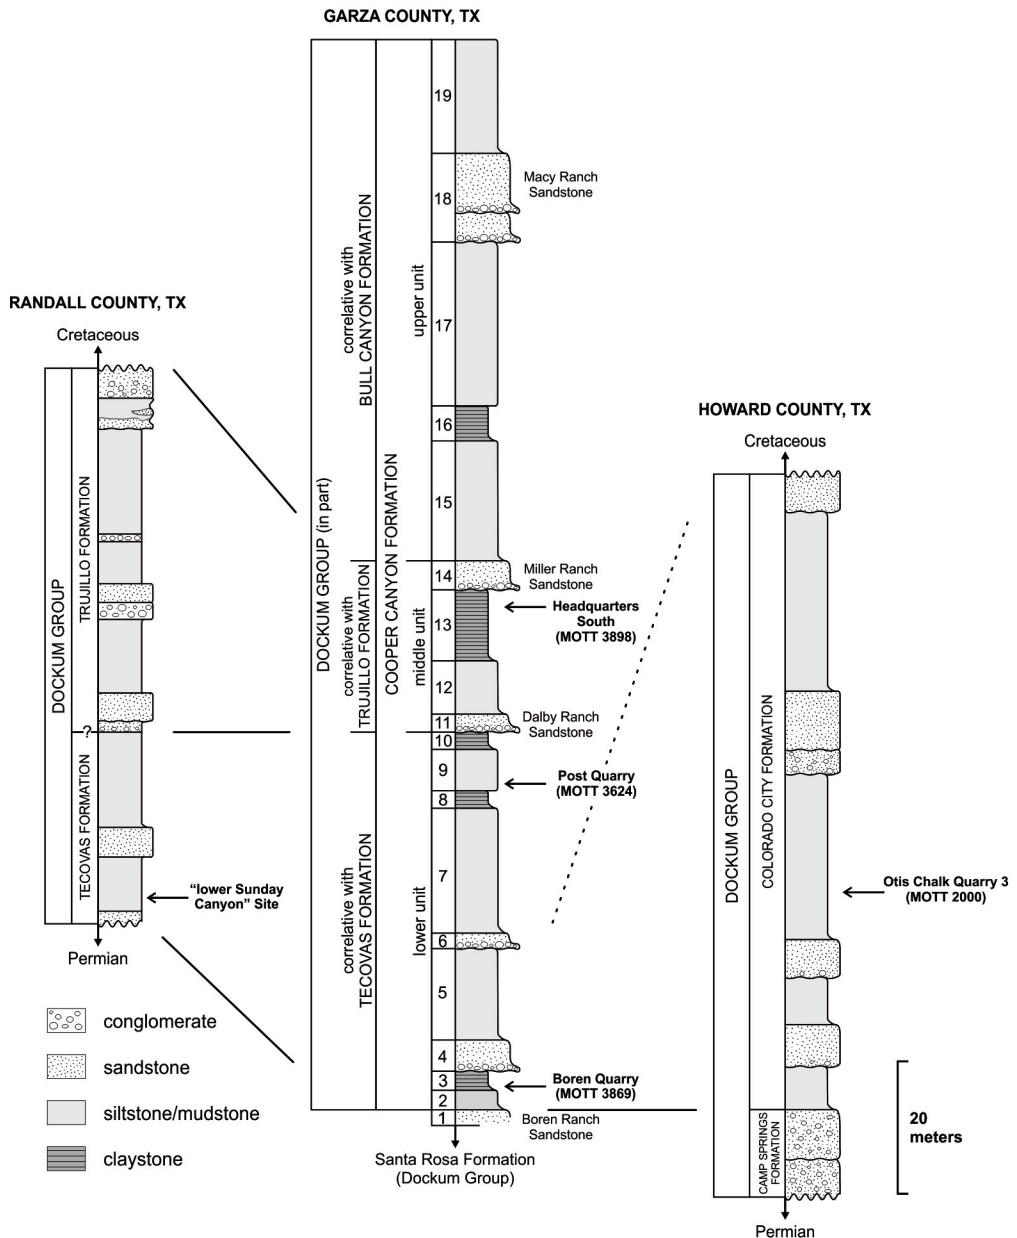

FIGURE 2. Generalized columnar sections of the Dockum Group in Texas in Randall, Garza and Howard counties, including the stratigraphic positions of the cited quarries in bold (modified after Ash, 1976; Lucas and Anderson, 1993b; Martz, 2008; Martz et al., 2013; and Bill Mueller, personal commun., 2014, 2015). Unit numbers and lithostratigraphic correlatives for the Garza County section are taken from Martz et al. (2013).

stone unit overlying a massive sandstone layer in southeastern Garza County, but the name Cooper was preoccupied by a Tertiary marl unit (Cooke and MacNeil, 1952). As its suggested lithostratigraphic equivalent in the Dockum Group of New Mexico, the name Bull Canyon Formation was proposed as a nomenclatural replacement (Lucas and Hunt, 1989) with priority over the Cooper Canyon Formation, for which a new type section was mea-

sured in southern Garza County, as a replacement for the former Cooper Member (Lehman et al., 1992). Accordingly, the Cooper Canyon and Bull Canyon formations were taken as interchangeable, until it was realized that the sandstone layer, the Boren Ranch Sandstone of Frelier (1987), on which the Cooper Member was originally described (Chatterjee, 1986; Lehman et al., 1992) was misidentified as the Trujillo Formation. Therefore, the

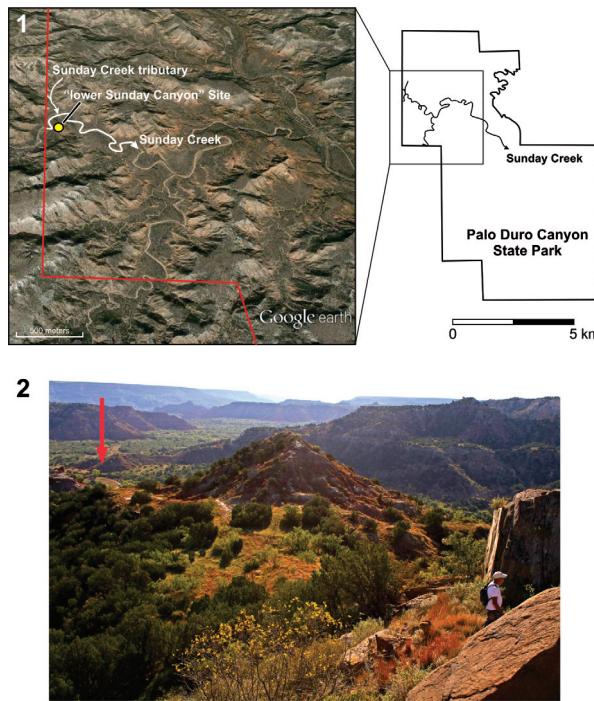

FIGURE 3. 1, Location map of the "lower Sunday Canyon" Site within the Palo Duro Canyon State Park (bordered in red on the map, taken from Google Earth 2016); 2, Field photograph of the "lower Sunday Canyon" Site, indicated by the red arrow (Photo credit: Bill Mueller).

Cooper Canyon Formation sensu Lehman (e.g., Lehman et al., 1992; Lehman, 1994a, 1994b; Lehman and Chatterjee, 2005) covers nearly all the Upper Triassic sediments above the Santa Rosa Formation in southern Garza County and cannot be used as a substitute for the Cooper Member. Martz (2008) employed the name Cooper Canyon Formation for the whole sequence overlying the Boren Ranch Beds, and subdivided it into lower, middle and upper units (Figure 2). Furthermore, it is firmly established that there is no evidence for a "Tr-4" unconformity in the Dockum Group of Texas (Martz, 2008) or in the Chinle Formation of Arizona (Woody, 2006; Parker and Martz, 2011).

In order to provide a fully-established lithostratigraphy, it is needed to reconcile the stratigraphic framework of the Dockum Group in southern Garza County with the rest of the Dockum outcrops in Texas and in New Mexico. Subsequent studies indicated that the lower, middle and upper units of the Cooper Canyon Formation in southern Garza County are equivalent to the Tecovas, Trujillo and Bull Canyon formations, respectively, in northern Garza, Crosby and in other northern Texas counties, and also in New Mexico (e.g., Cather et al.,

2013; Martz et al., 2013) (Figure 2). Lithostratigraphic equivalency of the Dockum Group exposures south to Garza County in Texas is pending and needs more detailed studies; nonetheless, the Colorado City Formation is considered here as a correlate of the lower part of the Tecovas Formation, following the original works of Lucas and Anderson (1993a, 1993b, 1995) (Figure 2).

There are five non-dinosaurian dinosauromorph bearing fossil localities in the Dockum Group of Texas (Figure 1). Boren Quarry (MOTT 3869) and Post Quarry (MOTT 3624) are the two well-known fossil localities from the Garza County that produced a prolific vertebrate assemblage (e.g., Lehman and Chatterjee, 2005; Martz et al., 2013). In the stratigraphic column, they roughly represent the bottom and top levels of the lower unit of the Cooper Canyon Formation, respectively (Figure 2). *Technosaurus smalli* (TTU-P9021, holotype) is one of the previously published non-dinosaurian dinosauromorph specimens from the Post Quarry, together with a complete left femur of *Dromomeron gregorii* (TTU-P11282) and a left dinosauriform tibia, which cannot be assigned to a specific taxon (TTU-P11127) (Chatterjee, 1984; Sereno, 1991; Hunt and Lucas, 1994; Irmis et al., 2007a; Nesbitt et al., 2007; Nesbitt and Chatterjee, 2008; Martz et al., 2013). Another fruitful locality from the Garza County is Headquarters South (MOTT 3898) that is placed at the upper part of the middle unit of the Cooper Canyon Formation, a direct correlative of the Trujillo Formation (Figure 2).

The Otis Chalk Quarry 3 (MOTT 2000) and the "lower Sunday Canyon" site are situated in Howard and Randall counties, respectively (Figures 1 and 3). The "lower Sunday Canyon" site (34°57.530' N 101°42.099' W) is located in the eastern end of the Little Fox Canyon within the Palo Duro Canyon State Park where a small tributary joins the Sunday Creek almost due north of the locality (Figure 3). The "lower Sunday Canyon" Site belongs to the lowermost portion of the Tecovas Formation and is placed slightly lower than the Otis Chalk Quarries in the stratigraphic column (Bill Mueller, personal commun., 2015) (Figures 2 and 4). The Otis Chalk quarries include beds from the middle portion of the Colorado City Formation (Lucas and Anderson, 1993b; Lucas et al., 1993) (Figure 2). The holotype of *Dromomeron gregorii* (TMM 31100-1306) and associated paratypes were collected from the Otis Chalk Quarry 3 (Nesbitt et al., 2009).

MATERIALS AND METHODS

Nine basal dinosauromorph specimens are described here. Most of the specimens (TTU-P12537X, TTU-P12539X, TTU-P18331, TTU-P20046, TTU-P10546 and TTU-P19803) were collected from the southeastern outcrops of the Doc-

kum Group of Texas and are reposed in the Museum of Texas Tech University (MoTTU). The dinosauromorph specimens from the Dockum Group of Texas (TTU-P specimens) were collected by Sankar Chatterjee and his crew, especially by Bill Mueller and Doug Cunningham, since the 1980s. The matrix covering the bone surfaces was

Arrow indicates anterior side.

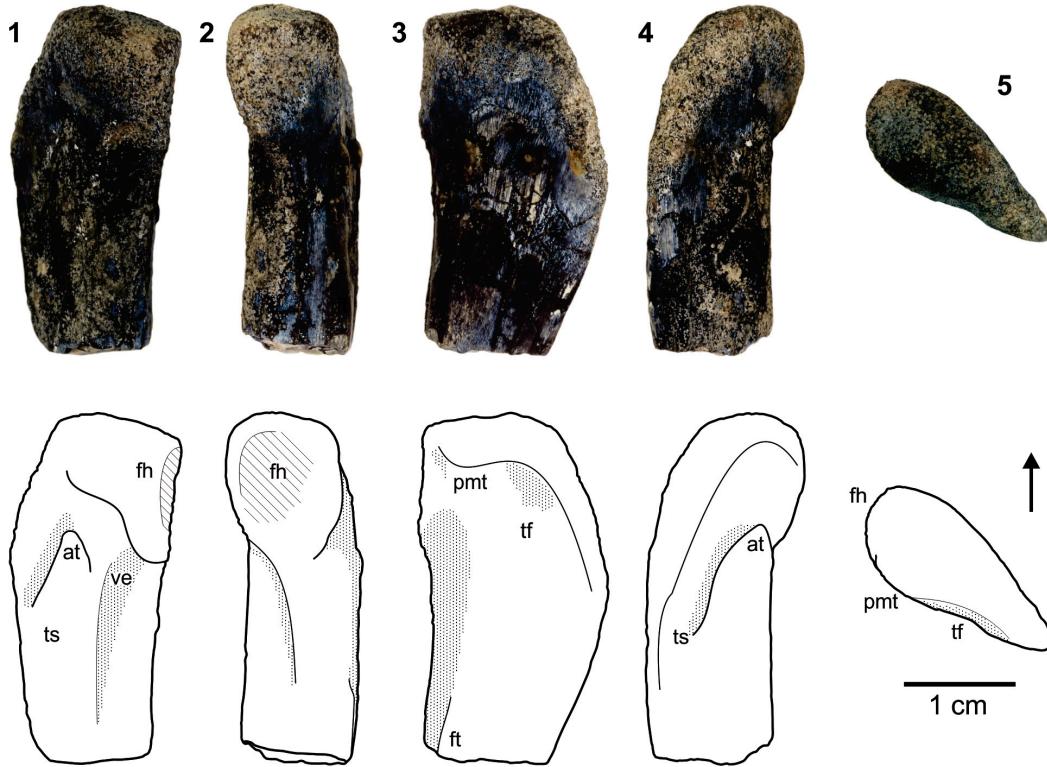

FIGURE 7. *Dromomeron gregorii* (WTAMU-V-8302), proximal end of right femur in 1, anterior view; 2, medial view; 3, posterior view; 4, lateral view; 5, proximal view. Abbreviations: **at**, anterior trochanter; **fh**, femoral head; **ft**, fourth trochanter; **pmt**, posteromedial tuber; **tf**, trochanteric fossa; **ts**, trochanteric shelf; **ve**, ventral emargination. Hatching indicates the damaged areas. Arrow indicates anterior side.

removed mechanically in the MoTTU fossil preparation lab, and photographs were taken by a professional photographer (Bill Mueller). Three additional specimens (WTAMU-V-8301, WTAMU-V-8302 and WTAMU-V-8303) were loaned from West Texas A&M University (WTAMU). These three specimens were recovered from a prepared pile of assorted bone fragments collected from the same stratigraphic horizon by Gerald E. Schultz from Palo Duro Canyon State Park (i.e., the "lower Sunday Canyon" Site). The corresponding information about the collection site and catalog numbers for these specimens were also obtained from G.E. Schultz. The preliminary data for all the TTU-P and WTAMU specimens were included in an unpublished dissertation (Sarıgül, 2014), whereas the voucher information for type specimens of *Dromomeron gregorii* collected from the Otis Chalk Quarry 3 (MOTT 2000) refers to the original publication of Sterling Nesbitt and his colleagues (2009).

SYSTEMATIC PALAEONTOLOGY

ARCHOSAURIA Cope 1869 sensu Gauthier, 1986
DINOSAUROMORPHA Benton, 1985
LAGERPETIDAE Arcucci 1986 sensu Nesbitt et al., 2009
Dromomeron gregorii Nesbitt et al., 2009
Figures 4-8

Material. Proximal end of left femur (TTU-P18331) and distal end of left femur (TTU-P20046) from the Post Quarry (MOTT 3624); proximal end of right femur (WTAMU-V-8302) and proximal end of right tibia (WTAMU-V-8303) from the "lower Sunday Canyon" Site (Figure 4).

Description and remarks. Although the damaged tip of the femoral head obliterates the anteromedial tuber, the posteromedial tuber of TTU-P18331 is well preserved (Figure 5). The trochanteric fossa is situated posteriorly. The anterior trochanter with a trochanteric shelf is distinct as a rugose ridge on the anterolateral side. The fourth trochanter bulges out more distally on the posteroventral side. The enlarged posteromedial tuber is the most conspicuous lagerpetid character of TTU-P18331, and this

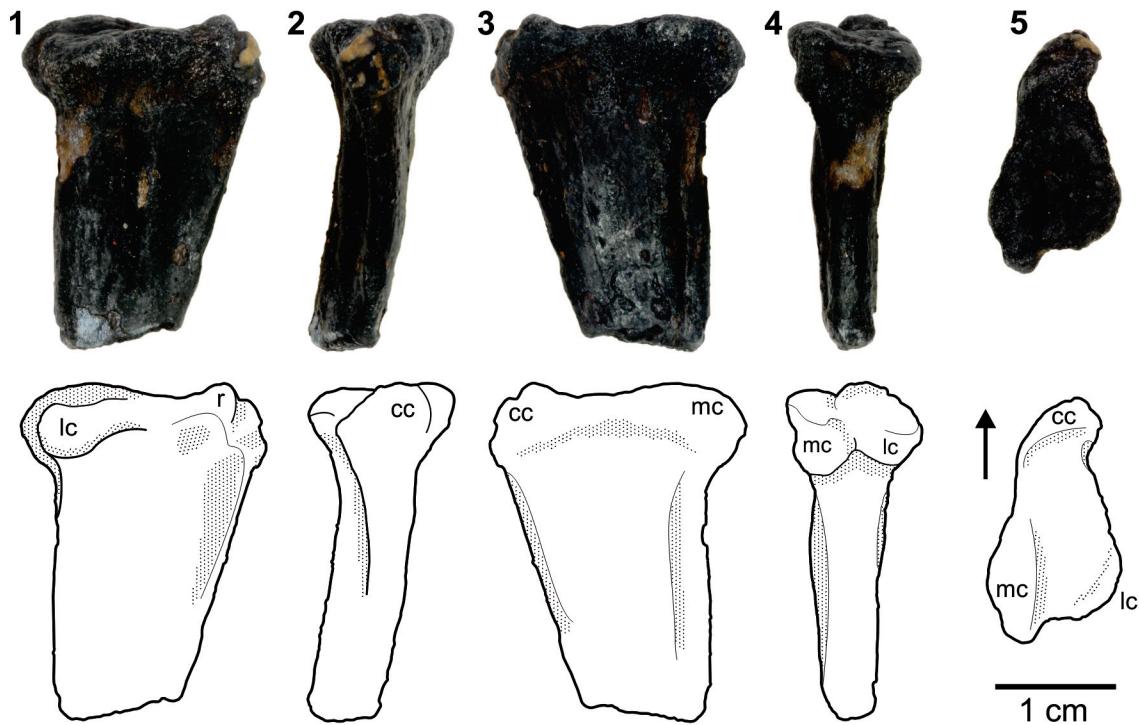

FIGURE 8. *Dromomeron gregorii* (WTAMU-V-8303), proximal end of right tibia in 1, lateral view; 2, anterior view; 3, medial view; 4, posterior view; 5, proximal view. Abbreviations: cc, cnemial crest; lc, lateral crest; mc, medial crest; r, ridge. Arrow indicates anterior side.

specimen can be assigned to *D. gregorii* based on the presences of an anterior trochanter with a trochanteric shelf and a fourth trochanter.

As in TTU-P11282 (Martz et al., 2013) and in all the specimens referred to *Dromomeron* (Nesbitt et al., 2009), the muscle scar for the *M. femorotibialis externus* is expressed as a rounded fossa that is slightly damaged in TTU-P20046 (Figure 6). The distal condyles are substantially enlarged compared to *D. romeri*, and the characteristic intercondylar groove between the medial and the fibular condyles is also highly reduced due to the relative enlargement of the latter.

Despite the fact that the anteromedial tuber of the femoral head is obliterated, the enlarged posteromedial tuber is quite distinct on WTAMU-V-8302, which represents an unequivocal lagerpetid character together with the ventral emargination located on the anteromedial side (Figure 7). As an expansion of the anterior trochanter, the trochanteric shelf provides a prominent and rugose muscle attachment surface. Only the proximal part of the fourth trochanter is preserved. An anterior trochanter with a trochanteric shelf and a fourth trochanter are typical traits of *D. gregorii* to which WTAMU-V-8302 is assigned.

The proximal surface of WTAMU-V-8303 is triangular and significantly longer in the anteroposterior direction (Figure 8). The cnemial crest is prominent with a small ridge on its tip, which is slightly projected laterally. A small lateral depression that stands posterior to the cnemial crest does not produce a strict sense tibial notch, since it does not extend down along the shaft. The lateral condyle is ventrally deflected and smaller than the medial, which is expanded posteriorly with a tapering tip, as in *D. gregorii*. The preserved portion of the shaft is mediolaterally compressed.

Dromomeron romeri Irmis et al. 2007b

Figures 4, 9-10

Material. Proximal end of right tibia (TTU-P12537X) from the Headquarters South locality (MOTT 3898); distal end of right femur (WTAMU-V-8301) from the "lower Sunday Canyon" Site (Figure 4).

Description and remarks. The proximal surface of TTU-P12537X is triangular and the three sides are almost equal in length (Figure 9). The cnemial crest is small but distinct, and its tip is slightly projected laterally. Posterior condyles are aligned, not pronounced and separated by a very shallow cleft.

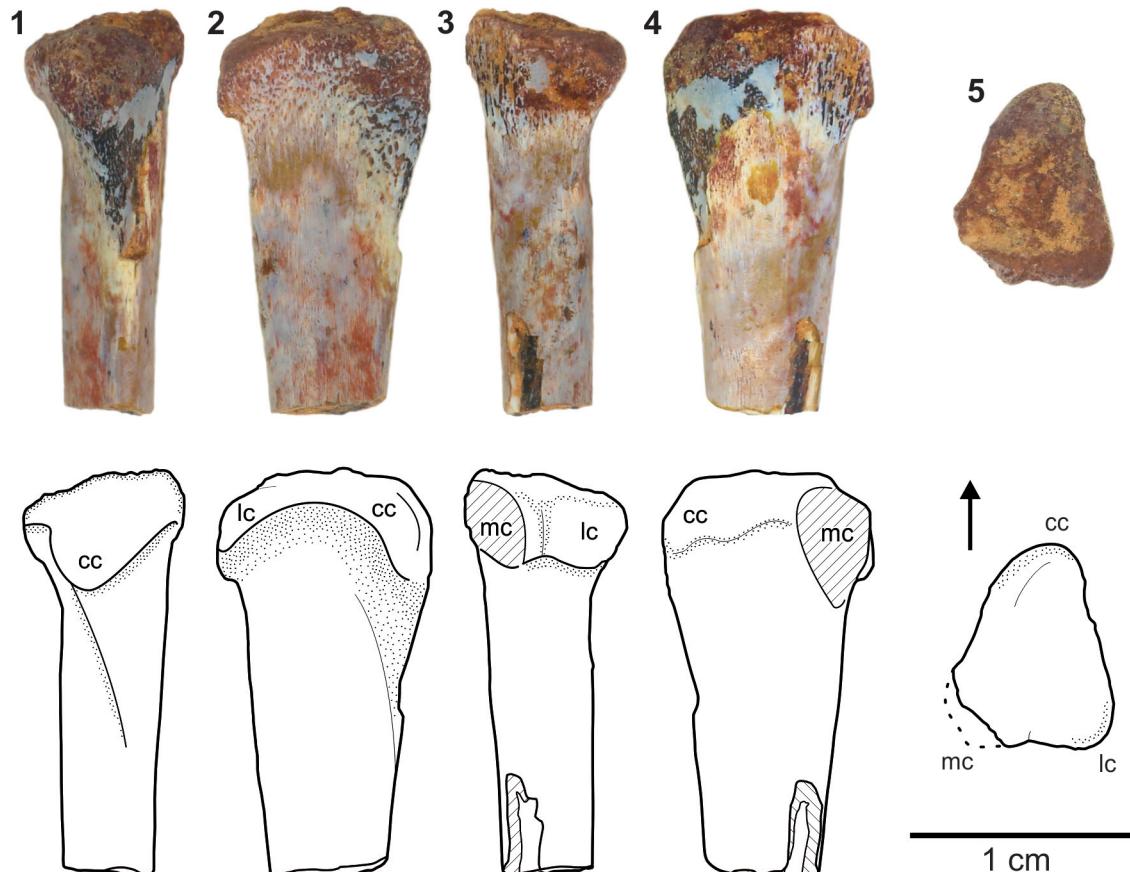

FIGURE 9. *Dromomeron romeri* (TTU-P12537X), proximal end of right tibia in **1**, anterior view; **2**, lateral view; **3**, posterior view; **4**, medial view; **5**, proximal view. Abbreviations: **cc**, crenial crest; **lc**, lateral condyle; **mc**, medial condyle. Hatching indicates the damaged areas. Arrow indicates anterior side.

The lateral condyle is ventrally deflected, as diagnostic of *Dromomeron* (Nesbitt et al., 2009). Even though the medial condyle is obliterated, the posterior condyles seem to be aligned and sub-equal in size, a character that is more comparable to *D. romeri* (see Irmis et al., 2007b, figure 2; Nesbitt et al., 2009, figure 4).

The slender shaft of WTAMU-V-8301 significantly widens distally with a distinct ridge on the anteromedial side that establishes its affinity to *Dromomeron romeri* (Irmis et al., 2007b) (Figure 10). The distal end is much larger mediolaterally than anteroposteriorly. Condyles are small and gracile as noted for *D. romeri* (Nesbitt et al., 2009). Medial and fibular condyles are well separated by the intercondylar groove.

Dromomeron sp.
Figures 4, 11

Material. Proximal end of right femur (TTU-P12539X) from the Headquarters South locality (MOTT 3898) (Figure 4).

Description and remarks. The head (or capitulum) of the proximal femur is broken but its hooked morphology of a typical lagerpetid is still traceable (Figure 11). The posteromedial tuber and adjacent trochanteric fossa (facies articularis antitrochanterica) are distinct. Right below the broken capitulum, a very faint emargination is present on the antero-lateral side. The femoral shaft bears no anterior trochanter or a trochanteric shelf; the absence of which was previously noted for *D. romeri* and also for the smaller specimens of *D. gregorii*. Unfortunately, the inadequate preservation prevents a species-level assignment for this specimen.

DINOSAUROMORPHA Benton, 1985
DINOSAURIFORMES Novas, 1992
Gen et sp. indet.
Figures 4, 12-13

Material. Left fibula (TTU-P10546) and distal end of left fibula (TTU-P19803) from the Boren Quarry (MOTT 3869) (Figure 4).

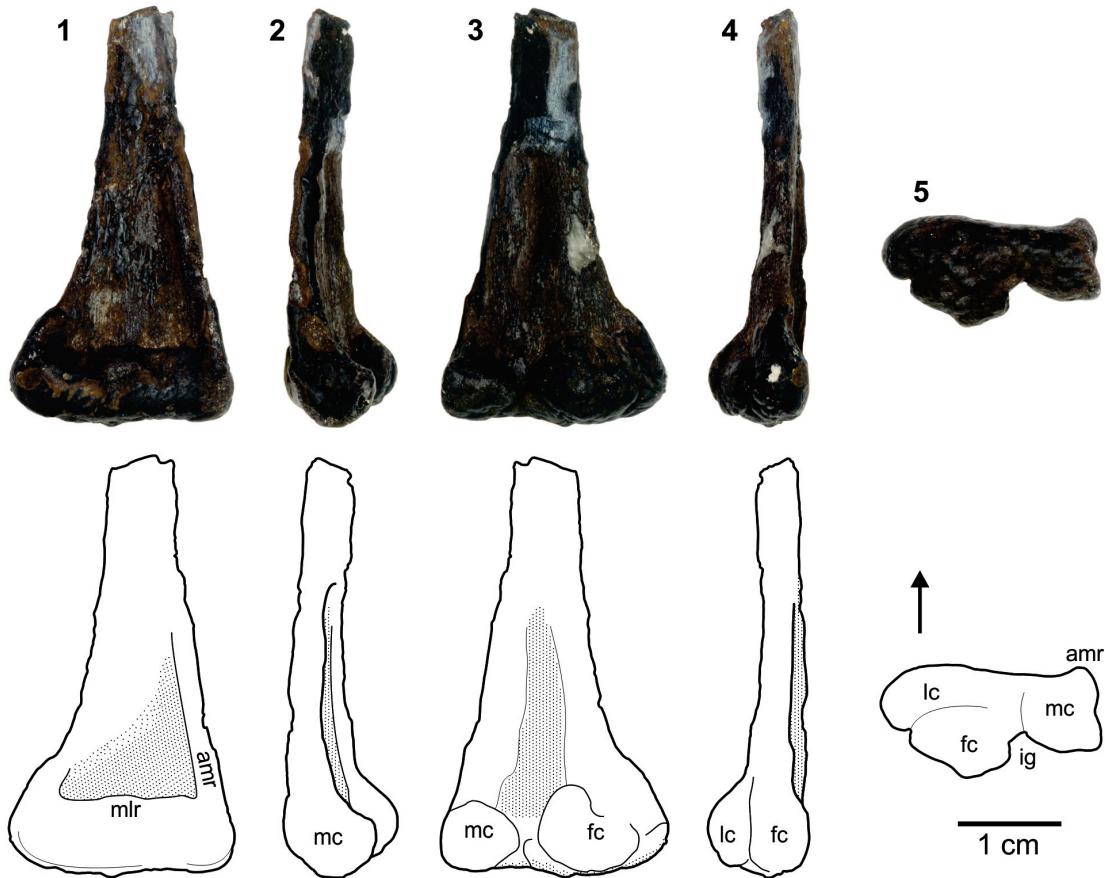

FIGURE 10. *Dromomeron romeri* (WTAMU-V-8301), distal end of right femur in 1, anterior view; 2, medial view; 3, posterior view; 4, lateral view; 5, distal view. Abbreviations: **amr**, anteromedial ridge (sensu Irmis et al., 2007b); **fc**, fibular condyle; **ig**, intercondylar groove; **lc**, lateral condyle; **mc**, medial condyle; **mlr**, mediolateral ridge. Arrow indicates anterior side.

Description and remarks. TTU-P10546 represents a complete and mediolaterally compressed left fibula (Figure 12). The proximal articulation is elongated in the anteroposterior direction and slightly altered around the edges. The anterior end of the proximal portion tapers smoothly with the missing tip and slightly curved anteromedially. The lateral corner of the posterior end is projected posterolaterally. The shaft is straight, slender, transversely compressed and considerably damaged where the attachment site for the *M. iliofibularis* was to be detected. The anterior and lateral borders of the distal end are rounded, whereas the posterior corner is expanded posteroventrally and becomes a prominent process. The reflection of this process on the distal surface is a small pyramidal tuberosity. There are two attachment surfaces detected on the distal surface. The lateral attachment surface is concave, extending from the posterior side towards the slightly raised medial side. This helical morphology of the lateral attachment

surface probably conforms to the unevenly raised articular facet formed by astragalus and calcaneum. The medial attachment surface is located on the posteromedial side of the distal surface and bears a slight bevel expressed on the anteromedial portion. This is visible in both medial and distal views, probably articulating with the lateral edge of the ascending process of the astragalus.

The proximal end and shaft of TTU-P10546 have the typical plesiomorphic dinosauromorph morphology (e.g., Langer, 2004; Nesbitt, 2011), and the main indicative of its affinity is probably the configuration of the distal end, which differs substantially from the lagerpetid and dinosaurian condition. The lagerpetid distal part of fibula is documented only in *Lagerpeton chanarensis* (Sereno and Arcucci, 1993), where both anterior and posterior ends of the convex distal articular surface are elongated and tapering over the tibia and astragalus, respectively. In *Silesaurus opolensis* and in basal saurischians, on the other hand,

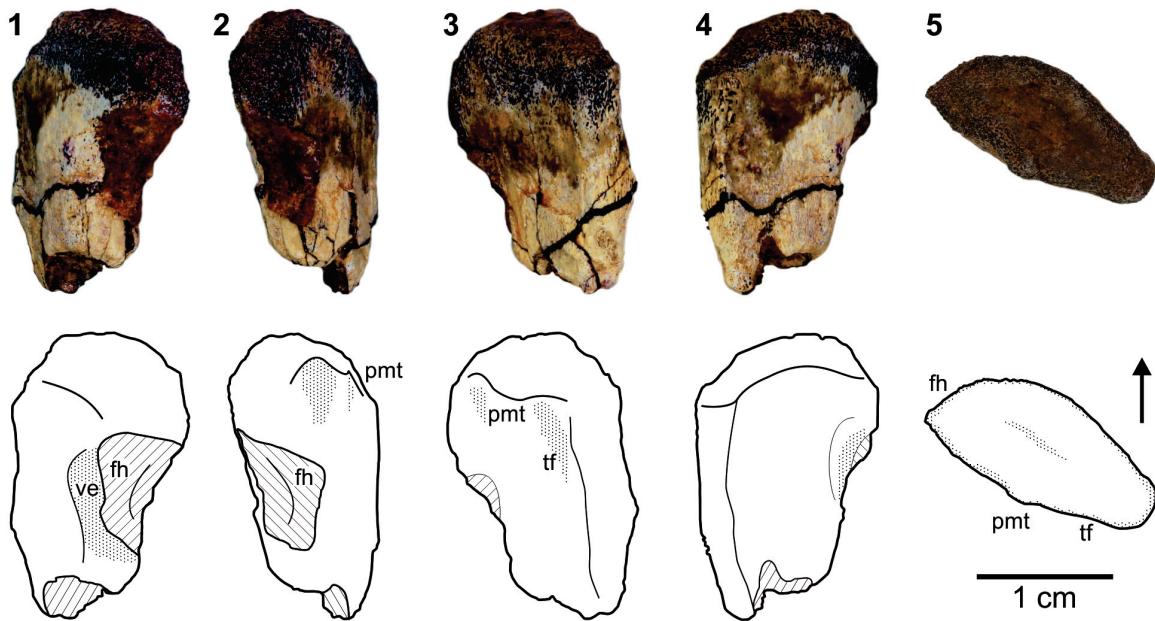

FIGURE 11. *Dromomeron* sp. (TTU-P12539X), proximal end of right femur in **1**, anterior view; **2**, medial view; **3**, posterior view; **4**, lateral view; **5**, proximal view. Abbreviations: **fh**, femoral head (note that the femoral head is broken); **pmt**, posteromedial tuber; **tf**, trochanteric fossa; **ve**, ventral emargination. Hatching indicates the damaged areas. Arrow indicates anterior side.

the distal surface of the fibula is flattened, and it is widened in anteroposterior (or anteromedial-posterolateral) axis with a distinct posterior tuber (e.g., Novas, 1993; Bonaparte et al., 1999; Langer, 2003; Dzik, 2003, figure 13C; Sereno et al., 2013). The basal ornithischian condition is even more peculiar; the fibula is reduced to a rod, where the distal portion is significantly twisted and fused to the tibia and astragalocalcaneum (e.g., Butler, 2005; Butler et al., 2010; Norman et al., 2011). *Pisanosaurus mertii* somewhat differs from the typical ornithischian condition by lacking the distal torsion and yielding an expanded distal end (Bonaparte, 1976; Norman et al., 2004).

The distal portion of the fibula of *Marasuchus lilloensis* offers the best comparison for TTU-P10546. Following the original description of Sereno and Arcucci (1994), the distal portion of the *M. lilloensis* fibula possesses an elliptical distal surface that is anteroposteriorly concave but mediolaterally convex with a distinct bevel on the medial side. A prominent tuber is present on the posterior corner, as described for TTU-P10546. In both taxa, the enlargement of the posterior tuberosity forms an asymmetrical distal end uniquely among ornithodirans (Nesbitt, 2011, character 345), differing from the posterodistal inclination on the flattened

lateral border of the distal fibula seen in some basal saurischians like *Eoraptor lunensis* and *Hererasaurus ischigualastensis* (Novas, 1993; Sereno et al., 2013). However, the medial edge is more rounded and the subdivision of the articular facets, if present, is less conspicuous in the distal part of the *M. lilloensis* fibula (Sereno and Arcucci, 1994, figure 12A). There is also a notable size difference between the two fibulae; the maximum length of the *M. lilloensis* fibula is about 7 cm (Sereno and Arcucci, 1994, table 5), whereas TTU-P10546 is more than three times longer (24 cm).

Since only the distal end of TTU-P19803 is preserved, the overall morphology and size is similar to those of TTU-P10546; only slightly more compressed mediolaterally (Figure 13). The lateral and anterior borders are rounded; a prominent process occurs on the posterior side that is followed by a small pyramidal tuberosity on the distal surface. The lateral and medial articulation surfaces seen in TTU-P10546 are not discernable in TTU-P19803; the tarsal articulation surfaces are represented by a single concave surface that is raised towards the medial side. This pattern is more compatible to that observed for *M. lilloensis* (Sereno and Arcucci, 1994, figure 12A).

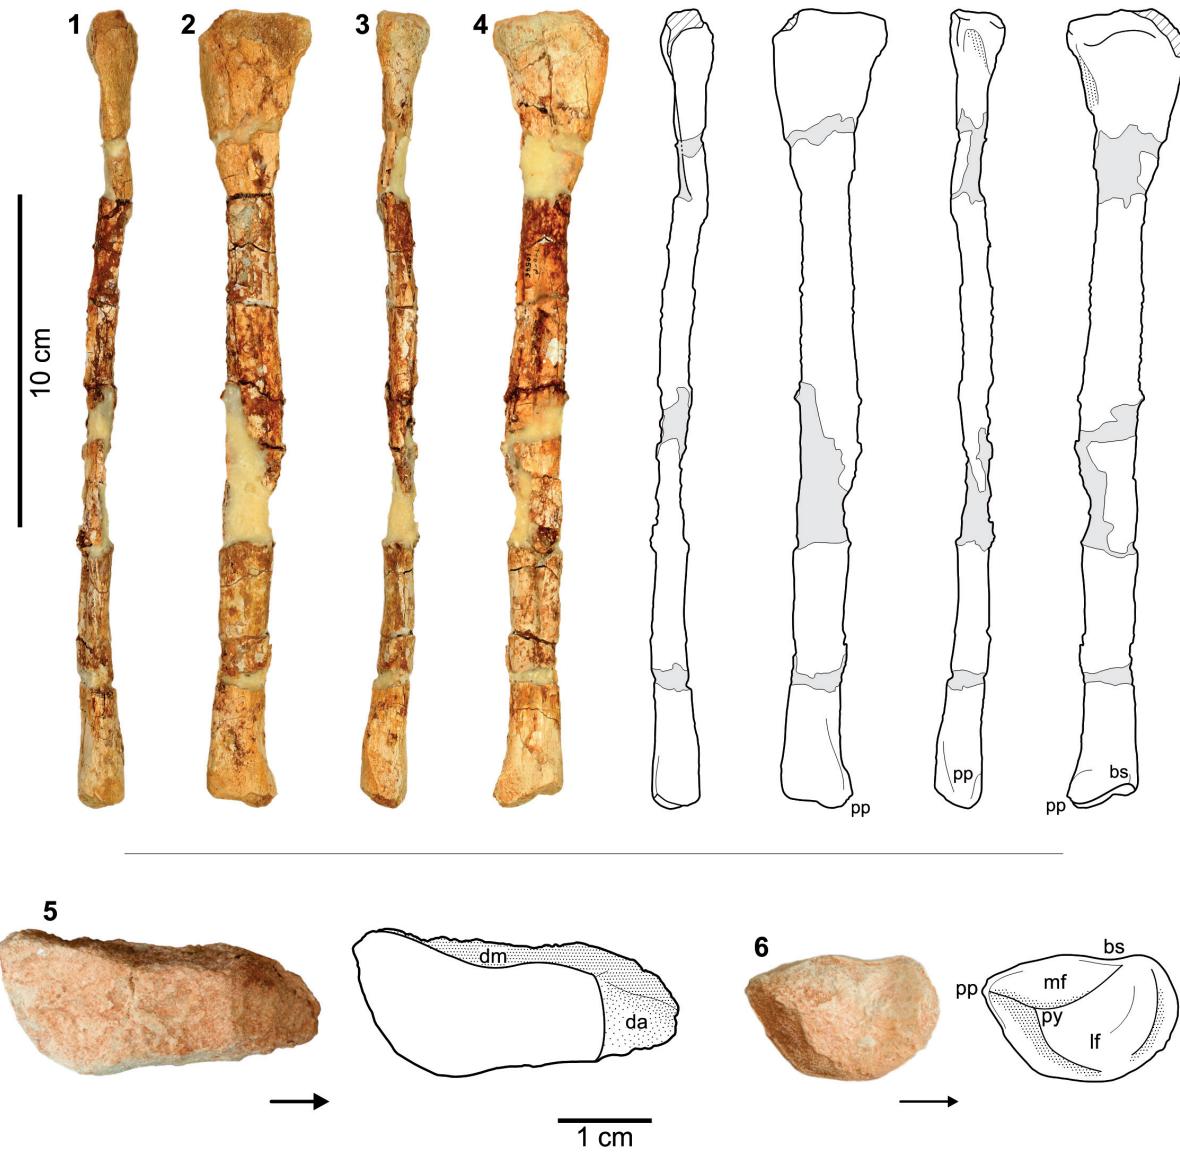

FIGURE 12. Dinosauriformes gen. and sp. indet. (TTU-P10546), left fibula in **1**, anterior view; **2**, lateral view; **3**, posterior view; **4**, medial view; **5**, proximal view; **6**, distal view. Abbreviations: **bs**, beveled surface; **da**, damaged anterior part; **dm**, damaged posterior part; **If**, lateral facet; **mf**, medial facet; **pp**, posterior process; **py**, pyramidal process. Arrow indicates anterior side.

CONCLUSION AND DISCUSSIONS

The dinosauromorph record of the Dockum Formation is important for understanding the distribution of ornithodirans in southern North America. Basal dinosauromorph specimens are presently unknown from the Dockum Group of New Mexico, leaving the Texas specimens as the only current record. Previously published specimens include the type specimens of *Dromomeron gregorii* (TMM 31100-1306 and associated paratypes), a left femur referred to *D. gregorii* (TTU-P11282), the

holotype of the silesaurid *Technosaurus smalli* (TTU-P9021), and an isolated tibia possibly attributable to a silesaurid (TTU-P11127). The new non-dinosaurian dinosauromorph specimens described here are referred to *Dromomeron romeri* (TTU-P1253X7; WTAMU-V-8301), *Dromomeron gregorii* (TTU-P18331; TTU-P20046; WTAMU-V-8302; WTAMU-V-8303) and *Dromomeron* sp. (TTU-P12539X), with two remaining specimens (TTU-P10546; TTU-P19803) assigned to Dinosauriformes indet. based on their morphologic similarities to the fibula of *Marasuchus lilloensis*,

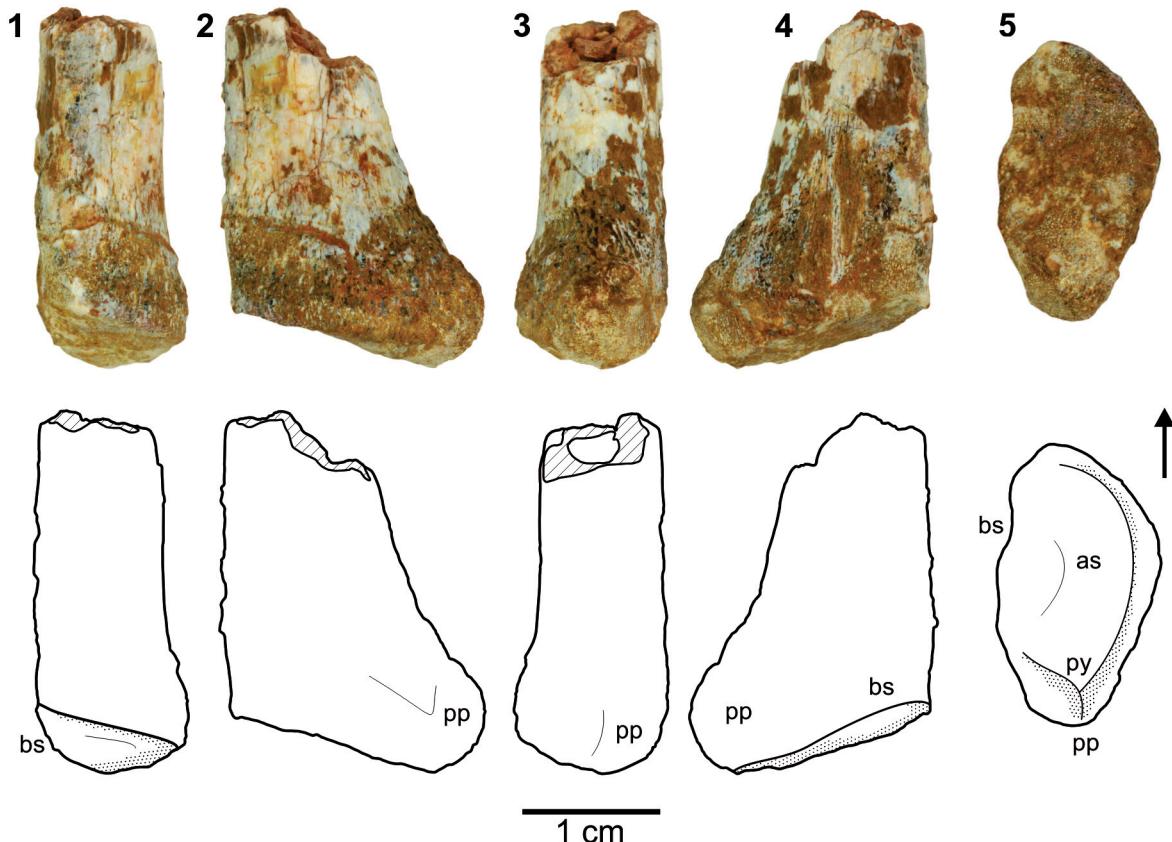

FIGURE 13. Dinosauriformes gen. and sp. indet. (TTU-P19803), distal end of left fibula in **1**, anterior view; **2**, lateral view; **3**, posterior view; **4**, medial view; **5**, distal view. Abbreviations: **as**, articular surface for astragalus and calcaneum; **bs**, beveled surface; **pp**, posterior process; **py**, pyramidal process. Hatching indicates the damaged areas. Arrow indicates anterior side.

regardless of their different sizes (Figures 4-13). Despite the fragmentary nature of the specimens, it can be concluded that the Late Triassic non-dinosaurian dinosauromorph fauna of the Dockum Group was taxonomically diverse.

The stratigraphic distribution of the *Dromomeron* specimens also deserves special attention. Previously, the fossil record of *D. romeri* was restricted to the upper levels of the Chinle Formation (i.e., the Petrified Forest Member), whereas *D. gregorii* was collected from the lower levels of both Dockum and Chinle sequences. Since the Dockum Group and the Chinle Formation are coeval and lithostratigraphically equivalent (e.g., Cather et al., 2013), it has been questioned whether there is a possible temporal succession of the two species (Nesbitt et al., 2009). The *Dromomeron* fossil record in the Dockum Group of Texas supports this theory. In Garza County, specimens of *D. romeri* are collected from the middle unit of the Cooper Canyon Formation (TTU-P12537X), whereas *D.*

gregorii fossils are recorded only in the lower unit of the Cooper Canyon Formation (TTU-P18331; TTU-P20046) (Figures 2 and 4). Similarly, the Otis Chalk Quarry 3 (MOTT 2000) where the *Dromomeron gregorii* was discovered is located in a relatively low stratigraphic position within the Dockum Group (Figures 2 and 4). However, the discovery of specimens WTAMU-V-8301, WTAMU-V-8302 and WTAMU-V-8303 from the same stratigraphic horizon of the "lower Sunday Canyon" Site demonstrates the ranges of the two *Dromomeron* species overlap (Figure 4). These findings not only document the first co-occurrence of *D. romeri* and *D. gregorii*, but also represent the lowest occurrences of both *Dromomeron* species in North America. Moreover, WTAMU-V-8301 extends the taxon range of *D. romeri* down to the lower levels of the Tecovas Formation, a situation implying that *D. romeri* existed during most of the Late Triassic. Concurrently, the suggested replacement of *D. gregorii* by *D. romeri* at the Adamanian-Revueltian

faunal transition (Parker and Martz, 2011) seems to reflect a sampling bias.

Now, the extension of the *D. gregorii* range gains importance to test the possible extinction of this taxon at the Adamanian-Revueltian boundary. The Post Quarry (MOTT 3624) and the *Placerias* Quarry of the Sonsela Member (Ramezani et al., 2014) are the two uppermost quarries from the Dockum Group and the Chinle Formation from where *D. gregorii* fossils were obtained (Nesbitt et al., 2009; Martz et al., 2013). Any future discovery of *D. gregorii* from the overlying sequences will show that this taxon was not affected by this Late Triassic faunal turnover, just like *D. romeri*. Therefore, *Dromomerion* taxon ranges should be refined with additional sampling in the future to further support these faunal turnover inferences.

ACKNOWLEDGEMENTS

The author owes special thanks to S. Chatterjee for providing the material and workspace, to G.E. Schultz and B. Mueller for sharing their personal data and observations, and to the Museum of Texas Tech University staff for their friendly attitude.
